## ABSTRACT

Radial velocity (RV) perturbations induced by stellar surface inhomogeneities including spots, plages and granules currently limit the detection of Earth-twins using Doppler spectroscopy. Such stellar noise is poorly understood for stars other than the Sun because their surface is unresolved. In particular, the effects of stellar surface inhomogeneities on observed stellar radial velocities are extremely difficult to characterize, and thus developing optimal correction techniques to extract true stellar radial velocities is extremely challenging. In this paper, we present preliminary results of a solar telescope built to feed full-disk sunlight into the HARPS-N spectrograph, which is in turn calibrated with an astro-comb. This setup enables long-term observation of the Sun as a star with state-of-the-art sensitivity to RV changes. Over seven days of observing in 2014, we show an average  $50 \text{ cm s}^{-1}$  RV rms over a few hours of observation. After correcting observed radial velocities for spot and plage perturbations using full-disk photometry of the Sun, we lower by a factor of two the weekly RV rms to  $60 \text{ cm s}^{-1}$ . The solar telescope is now entering routine operation, and will observe the Sun every clear day for several hours. We will use these radial velocities combined with data from solar satellites to improve our understanding of stellar noise and develop optimal correction methods. If successful, these new methods should enable the detection of Venus over the next two to three years, thus demonstrating the possibility of detecting Earth-twins around other solar-like stars using the RV technique.

*Key words:* instrumentation: spectrographs – planets and satellites: detection – techniques: radial velocities

## 1. INTRODUCTION

The radial velocity (RV) technique is successful at finding super-Earth planets orbiting bright stars (Howard et al. 2010; Mayor et al. 2011), as well as extremely short period Earth-mass planets (Dumusque et al. 2012; Howard et al. 2013; Pepe et al. 2013; Dumusque et al. 2014b; Dressing et al. 2015). However, RV detection of Earth-twins, i.e., long-period terrestrial worlds around solar-type stars, requires an order of magnitude improvement in precision to  $\sim 10 \text{ cm s}^{-1}$ . Among the multitude challenges to reaching such RV precision, the most important ones are: (i) stable, long-term wavelength calibration of the astrophysical spectrograph; and (ii) accounting for the effects of stellar noise, i.e., RV perturbations induced by stellar surface inhomogeneities, which are typically a few  $\text{m s}^{-1}$  for solar-type stars. The first challenge has been successfully addressed with astro-comb calibrators, based on laser frequency combs locked to atomic clocks (Wilken et al. 2010, 2012; Phillips et al. 2012; Glenday et al. 2015). To meet the second challenge, it will be crucial to better understand RV noise induced by stars and develop mitigation techniques, particularly as current and future high-resolution spectrographs such as HARPS (with its newly commissioned astro-comb, Mayor et al. 2003; Wilken et al. 2012), HARPS-N (Cosentino et al. 2012), ESPRESSO (Pepe et al. 2014), and G-CLEF (Szentgyorgyi et al. 2014) should reach long-term instrumental RV precision allowing Earth-twin detection.

Stellar RV noise can be differentiated into four categories (given the current state of knowledge):

1. stellar oscillations, on a timescale of a few minutes for solar-like stars, produced by pressure waves propagating in stellar interiors (Kjeldsen et al. 2005; Arentoft et al. 2008; Dumusque et al. 2011c);
2. stellar granulation and supergranulation, on a timescale from a few minutes to 48 hr, resulting from convectively driven outflowing material reaching the stellar surface (Del Moro 2004; Del Moro et al. 2004; Dumusque et al. 2011c);
3. short-term stellar activity, on the timescale of the stellar rotational period, induced by rotation in the presence of evolving and decaying surface inhomogeneities including spots and plages (e.g., Saar & Donahue 1997; Saar 2009; Meunier et al. 2010; Boisse et al. 2012; Dumusque et al. 2014a; Borgniet et al. 2015); and
4. long-term stellar activity, on a timescale of several years, induced by stellar magnetic cycles and/or surface flows (Makarov 2010; Dumusque et al. 2011a; Lovis et al. 2011; Meunier & Lagrange 2013).

Due to their semi-periodic nature, stellar oscillations can be averaged out efficiently by taking measurements with exposure times longer than the timescale of these perturbations (Dumusque et al. 2011c). This observational strategy is now commonly employed in high precision RV surveys, e.g., by imposing a minimum exposure time of fifteen minutes. Stellar

**Figure 1.** High signal-to-noise solar spectrum centered on the Sodium lines (top) with its simultaneous astro-comb wavelength calibration (bottom) as observed by HARPS-N.

granulation can be mitigated somewhat by observing a star several times per night, with the maximum possible spread between measurements (Dumusque et al. 2011c). However, this approach is only partially effective, and better mitigation methods need to be developed. For short-term activity, some correction techniques have been investigated (Boisse et al. 2009, 2011; Aigrain et al. 2012; Meunier & Lagrange 2013), but none are fully satisfactory. Finally, long-term activity seems to correlate well with the calcium chromospheric activity index, which provides a promising approach to mitigation of this source of stellar RV noise (Dumusque et al. 2012; Meunier & Lagrange 2013).

Characterizing the effects of stellar noise sources on stellar spectra with sufficient precision to allow the detection of true Earth-twins from RV measurements is a challenging task. An orbiting planet will produce on the stellar spectrum a pure shift of all the spectral lines, while stellar noise will modify the shape of spectral lines. The two effects are different in nature and should be distinguishable. However, when considering an Earth-like planet orbiting a quiet star like the Sun, both the planetary and stellar signals will induce shifts or shape variations of spectral line smaller than a thousand of a detector pixel. Therefore, we cannot distinguish one effect from the other on single spectral lines. To get around the problem, we need to average thousands of spectral lines to construct observables that are sensitive to stellar noise. However this is extremely challenging as this noise affects each spectral line differently.

So far, it was only possible to obtain precise, frequent, full-disk RV measurements derived from the full optical spectrum for stars other than the Sun. However, the surfaces of other stars are not resolvable; and therefore all the information used to study surface inhomogeneities is indirect, including: photometric flux (e.g., Boisse et al. 2009; Aigrain et al. 2012), bisector of spectral lines or of the cross correlation function depending on the activity level of the star (e.g., Vogt et al. 1987; Queloz et al. 2001; Figueira et al. 2013; Dumusque et al. 2014a), or the calcium chromospheric activity index (Noyes et al. 1984). Because it is extremely difficult to infer from such indirect observables the size, location, and contrast of surface inhomogeneities, understanding in detail the RV perturbations produced by these features is a major challenge.

As a way forward, we note that we might better understand the effect of surface inhomogeneities on RVs by obtaining precise full-disk RV measurements of the Sun. This approach of observing the Sun as a star allows us to directly correlate any change in surface inhomogeneities observed by solar satellites like the *Solar Dynamics Observatory* (SDO; Pesnell et al. 2012) with variations in the full-disk RV. Thus, we built a small solar telescope to feed a full-disk unresolved image of the Sun into the HARPS-N spectrograph located at the Telescopio Nazionale Galileo at the Observatorio del Roque de los Muchachos, Spain. We plan to use this instrument to observe the Sun several hours every clear day over the next two to three years, employing the exquisite long-term  $\text{sub-m s}^{-1}$  precision of HARPS-N calibrated by an astro-comb. Note that this project is not the only one to feed full-disk sunlight into a high-precision spectrograph (Kjeldsen et al. 2008; Probst et al. 2015; Strassmeier et al. 2015). However, our setup observes the Sun using exactly the same instrumental configuration as for other HARPS-N targets, which allows for a direct comparison between solar and stellar spectra.

## 2. THE HARPS-N SOLAR TELESCOPE

The solar telescope is a simple instrument built from off-the-shelf components. Details of this instrument and its application to solar observations will be provided in a future publication (A. Glenday et al. 2015, in preparation). Here we provide a brief summary. The solar telescope consists of a  $3'' f = 200 \text{ mm}$  achromatic lens, which feeds an integrating sphere to scramble the solar disk. A guide camera mounted on the telescope frame provides sufficient guiding to keep the 2 mm solar image centered on a 6 mm input aperture. These components are mounted on an amateur telescope tracking mount following the Sun. The integrating sphere couples to a  $300 \mu\text{m}$  core optical fiber which is fed to the HARPS-N spectrograph via its calibration unit. Light from the Sun is coupled out of the integrating sphere to HARPS-N with a uniformity of better than  $10^{-4}$  as measured both in the laboratory and on-sky. This good uniformity is crucial to average out efficiently the  $4 \text{ km s}^{-1}$  RV shift that can be seen between the blueshifted approaching limb and the redshifted receding limb of the Sun. Given these  $4 \text{ km s}^{-1}$ , a uniformity

**Figure 2.** Left: solar radial velocities (RVs) after barycentric correction obtained by the HARPS-N solar telescope during one week using simultaneous astro-comb wavelength calibration. The RV rms over the week time span of the observation is  $133 \text{ cm s}^{-1}$ , and the daily RV rms is shown above each daily observations on the plot. Right: subset of RVs highlighting the daily variations seen on 2014 April 29 and May 1.

better than  $10^{-4}$  enables a quantitative comparison of disk-integrated RV below the  $10 \text{ cm s}^{-1}$  level.

The throughput of the solar telescope allows for exposures as short as 20 s. As described above, to reduce the effects of the solar 5-minute oscillations, we typically expose for five minutes to average over one such oscillation period. However, this instrument can also be used in its 20 s exposure time mode ( $\approx 45 \text{ s}$  including readout) where the five minute oscillation signal is easily observable (A. Glenday et al. 2015, in preparation). Such a mode may prove useful for asteroseismology studies, as well as testing the effectiveness of different exposure times and observing strategies for averaging out oscillation and granulation jitter.

### 3. FIRST TEST RESULTS

#### 3.1. Raw Solar RVs

We first observed the Sun for seven days between 2014 April and May using the simultaneous astro-comb wavelength calibration of HARPS-N to provide RV precision better than  $10 \text{ cm s}^{-1}$  for the instrumental drift (Phillips et al. 2012; Glenday et al. 2015). We selected an exposure time of five minutes for each observation to average out the signal induced by solar oscillations. Figure 1 displays one example of such an observation to highlight the high signal-to-noise solar spectrum obtained with its simultaneous astro-comb wavelength calibration ranging from 5000 to 6200 Å.

We derived the final RVs using a single wavelength solution and corrected for: (i) day-to-day instrumental drift using daily Thorium–Argon calibrations; and (ii) same day variations using the simultaneous reference fiber containing the astro-comb calibration. We show in Figure 2 the raw RVs obtained from the solar telescope only considering clear sky measurements. The presence of clouds in front of the solar disc will break the flux balance between the blueshifted approaching limb and the redshifted receding limb of the Sun and can easily create several dozens of  $\text{m s}^{-1}$  variations. The daily RV rms of our observations span a range between 37 and  $87 \text{ cm s}^{-1}$ ; however the day for which the rms is  $87 \text{ cm s}^{-1}$  is affected by an outlier. Over the week time span of this observing run, the RV rms increases to  $133 \text{ cm s}^{-1}$ . This RV drift could be explained by

**Figure 3.** Average daily RV rms (e.g., for 5 minutes the average of the values shown on the left of Figure 2) as a function of binning consecutive RV observations. The outlier on 2014 May 04 was not considered for this analysis. Note that for 120 minutes and larger binning, we do not have sufficient observations per day to give a reliable estimates of the average daily RV rms, which explains why the observed RV rms for 120 minutes is smaller than what is expected in the ideal case of white noise.

surface inhomogeneities evolving and moving on the solar disk because of the 25-day rotational period of the Sun.

The RVs for 2014 April 29 and May 1, as shown in the right plot of Figure 2, are affected by variations that exceed errors from photon noise. It is likely that this excess jitter is induced by long-period oscillation modes, and longer timescale stellar signals like granulation and supergranulation. However, it is too early to conclude at this point with so few measurements if this excess daily jitter is indeed induced by the Sun. Binning the measurements over timescales longer than 5 minutes, we observe that the average daily RV rms decreases, a sign of residual signals (see Figure 4). Stellar signals are known to be sources of red noise, which could explain the smaller decrease in RV rms with binning than what is expected for white noise. These issues will be studied in much greater detail once substantially larger numbers of observations have been collected.

**Figure 4.** *SDO* images taken on BJD = 2456780 (2014 May 2, 12:00 UT), which corresponds to the maximum RV of the first observation run. From left to right, it is possible to see an HMI intensity map of the Sun, a magnetogram (6173 Å), and a view of the Sun in extreme ultraviolet (171 Å) and in the far ultraviolet (1600 Å). It is clear that the Sun is active at this given time.

### 3.2. Correction for RV Drift Induced by Surface Inhomogeneities

We consulted the contemporaneous *SDO* images to check if the observed RV drift was caused by inhomogeneities present on the solar surface. In Figure 4, we show the *SDO* images of the Sun taken on BJD = 2456780 (2014 May 2, 12:00 UT), corresponding to the maximum RV of the first observing run. It is clear from the Helioseismic and Magnetic Imager (HMI Schou et al. 2012) intensity map and magnetogram that large surface inhomogeneities were present on the Sun at this time.

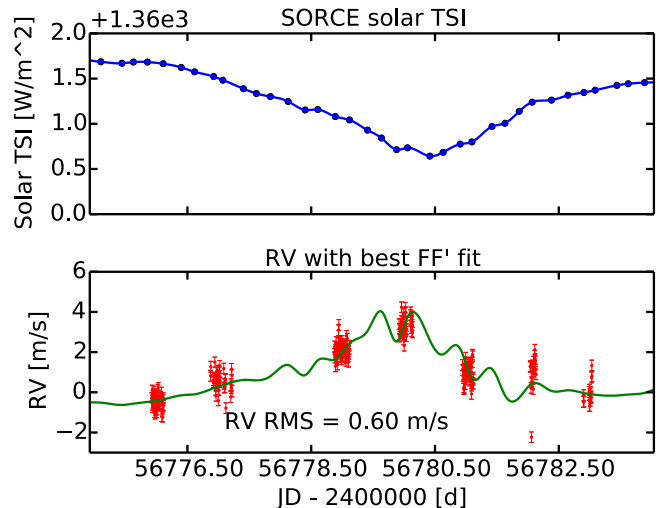

For a first order correction of the RV drift due to these surface inhomogeneities, we applied the  $FF'$  method proposed by Aigrain et al. (2012). These authors show that a simple model estimating the RV effect of spots and plages can link the RV variation to the flux variation using the following formula:

$$\Delta RV = a \times FF' + b \times F^2, \quad (1)$$

where  $F$  and  $F'$  correspond to the stellar flux and its time derivative. Parameters  $a$  and  $b$  are proportional to the relative flux drop for a spot at the disk center, the convective blueshift difference in the unspotted photosphere and that within the magnetized area, and the ratio of the area covered by plages to the one covered by spots.

To perform the fit of the RV data using the  $FF'$  method, we used data from the *SORCE* satellite (*SORCE* Collaboration 2015) that gives the total solar irradiance (TSI), i.e., the disk integrated flux, every 6 hr. We then interpolated the *SORCE* data to match the RV observations and hypothesized that both parameters  $a$  and  $b$  are constant on the timescale of the observing run. This is a reasonable argument considering that large spots and plages, which are likely responsible for the majority of the RV variation, are evolving on the timescale of a rotational period, i.e., 25 days (Howard 2000; Dumusque et al. 2011b). In Figure 5 the top panel shows the TSI as a function of time, and the bottom panel represents the RV of our observing run, with the best  $FF'$  fit in green. After removing the best  $FF'$  fit to the RVs, the residuals show an RV rms of  $60 \text{ cm s}^{-1}$  for the full observing run. This is an improvement of 55% compared to the RVs without the  $FF'$  correction.

In the studied dataset, the  $FF'$  method seems to perform efficiently in reducing the scatter induced by stellar noise. However, several studies have shown that  $FF'$  cannot explain fully the RV variation induced by stellar noise (Aigrain et al. 2012; Haywood et al. 2014). We therefore expect that the  $FF'$  method will not perform as well for future solar RV datasets,

**Figure 5.** Top: total solar irradiance (TSI) of the Sun as measured by the *SORCE* satellite. The dots represent the raw *SORCE* data, and the line is a cubic interpolation. Bottom: RVs obtained with the HARPS-N solar telescope. The green curve represent the best  $FF'$  fit to the data using the interpolated *SORCE* data. The RV rms of the residuals after subtracting the best  $FF'$  model is  $60 \text{ cm s}^{-1}$ .

and we want to investigate further the use of *SDO* images and dopplergrams in correcting for stellar noises.

## 4. CONCLUSION

First tests of the HARPS-N solar telescope show sub- $\text{m s}^{-1}$  RV precision over a week timescale. More extensive RV measurements with the same quality, combined with the wealth of information available from solar satellites, should allow us to develop a better understanding of the RV variation induced by solar surface inhomogeneities. We expect this will lead to better correction techniques for stellar noise applicable to bright stellar RV targets, and eventually will enable the RV detection of Venus, thus demonstrating the possibility of detecting Earth-twins around other stars using Doppler spectroscopy.
